Demographics and Real Interest Rates:

Inspecting the Mechanism*

Abstract

The demographic transition can affect the equilibrium real interest rate through three channels. An increase in longevity—or expectations thereof—puts downward pressure on the real interest rate, as agents build up their savings in anticipation of a longer retirement period. A reduction in the population growth rate has two counteracting effects. On the one hand, capital per-worker rises, thus inducing lower real interest rates through a reduction in the marginal product of capital. On the other hand, the decline in population growth eventually leads to a higher dependency ratio (the fraction of retirees to workers). Because retirees save less than workers, this compositional effect lowers the aggregate savings rate and pushes real rates up. We calibrate a tractable life-cycle model to capture salient features of the demographic transition in developed economies, and find that its overall effect is to lower the equilibrium interest rate by one and a half percentage points between 1990 and 2014. Through these channels, demographic trends have important implications for the conduct of monetary policy, especially in light of the zero lower bound on nominal interest rates. Other policies can offset the negative effects of the demographic transition on real rates with different degrees of success.

1 Introduction

Since the Global Financial Crisis (GFC), real interest rates in many developed economies have been in negative territory, as nominal interest rates hover around zero and inflation rates, although quite low for historical standards, have remained positive (in most countries, at least on average). This observation naturally brings forth the implication that accommodative monetary policies (both conventional and unconventional) that were put in place in response to the GFC are the reason behind ultra-low real rates, and that this phenomenon will be over as soon as central banks will begin the tightening cycle. Yet, a longer-term perspective immediately reveals a different perspective. Real interest rates have been trending down for more than two decades across many countries (Figure 1). These low-frequency movements suggest that forces other than accommodative monetary policies must be at play.

Demographic trends are a natural candidate explanation for low and declining real interest rates. The world is undergoing a dramatic demographic transition. In most advanced economies people tend to live longer. In Japan, the U.S. and Western Europe, life expectancy at birth has increased by about 10 years between 1960 and 2010 (Figure 2, left panel), and new generations have continued to expect longevity to increase. At the same time, immigration notwithstanding, population growth rates are decreasing at a fast pace, and in some cases (e.g. Japan) becoming negative (Figure 2, right panel).

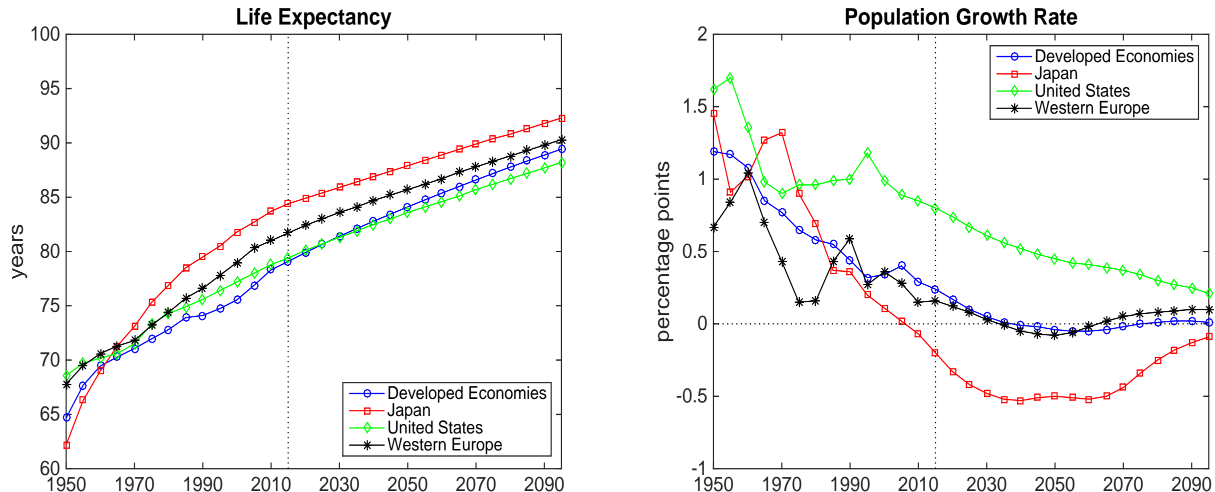

Figure 2: Left panel: Years of life expectancy at birth. Right panel: Population growth rate. Sample: Developed Economies (Northern America, Europe, Japan, Australia, New Zealand), Japan, United States, Western Europe. Source: United Nations World Population Prospects (2015 Revision).

The combination of the population growth slowdown and the increase in longevity implies a notable increase in the dependency ratio—i.e. the ratio between people 65 years and older and people 15 to 64 years old (Figure 3). The consequences of this demographic transition are far reaching and have important macroeconomic, public finance and political economic repercussions.[1]

In this paper, we focus on the consequences of the demographic transition for real interest rates. We illustrate three channels through which the demographic transition can affect the equilibrium real interest rate using a tractable life-cycle model. For a given retirement age, an increase in life expectancy lengthens the retirement period and generates additional incentives to save throughout the life cycle.[2] This effect tends to be stronger if agents believe that public pension systems will not be able to bear the additional burden generated by an aging population. Therefore, an increase in longevity—and expectations thereof—tends to put downward pressure on the real interest rate, as agents build up their savings in anticipation of a longer retirement period.

A drop in the growth rate of the population produces two opposite effects on real interest rates. On the one hand, lower population growth leads to a higher capital-labor ratio, which depresses the marginal product of capital. This "supply effect" is very much akin to a permanent slowdown in productivity growth, pushing down real interest rates. On the other hand, however, lower population growth eventually drives up the dependency ratio. Because retirees have a lower marginal propensity to save, this change in the composition of the population is akin to a "demand effect" that pushes up aggregate consumption, and puts upward pressure on equilibrium real interest rates.[3]

[1]See Nishimura (2011) for an excellent discussion of the connections between the demographic transition and the recent global financial crisis.

[2]Acemoglu and Johnson (2007) study the effects of increases in life expectancy on economic growth. Ferrero (2010) focuses the implication of differentials in life expectancy among advanced economies for international capital flows.

[3]Chen et al. (2009) and Ferrero (2010) find small effects of measured changes in population growth rates on the

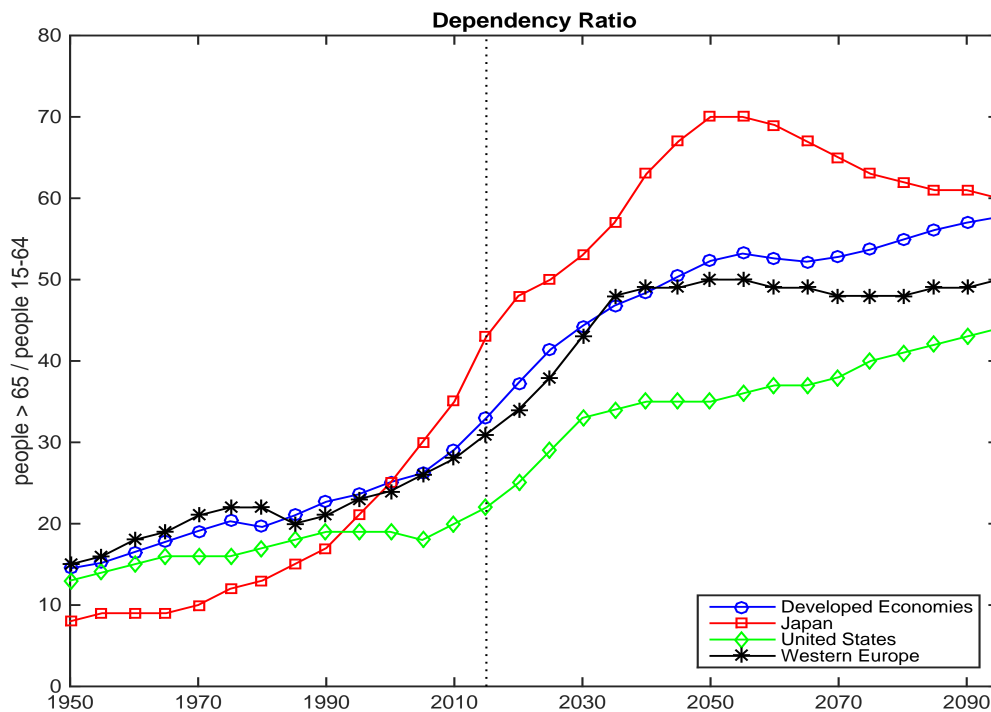

Figure 3: Dependency ratio. Sample: Developed Economies (Northern America, Europe, Japan, Australia, New Zealand), Japan, United States and Western Europe. Source: United Nations World Population Prospects (2015 Revision).

We allow for demographic developments in the model developed by Gertler (1999), who studies fiscal policy and social security with stationary population. We calibrate the model to capture salient features of the demographic transition in developed economies, and quantify the effects of the aforementioned channels. The overall effect of a prototypical demographic transition is to lower the equilibrium interest rate by a significant amount. In particular, for our "representative developed country," the equilibrium annual real rate falls by 1.5 percentage points between 1990 and 2014. The increase in life expectancy accounts for the bulk of the drop in the real interest rate.

We also provide some suggestive anecdotal cross-country evidence that the links between demographics and real interest rates implied by the calibrated model are present in the data. To that end, we compare how the short-term real interest rate varies across pairs of comparable countries, as a function of differences in life expectancy and changes in projected life expectancy (taken one at a time). That is, to provide some evidence on the relationship between real rates and life expectancy, say, we look for pairs of countries with similar changes in projected life expectancy, but with different actual life expectancies. We then see if the differences in their real rates relate to those differences in life expectancies in a way that is consistent with the implication of the calibrated model.

dynamics of U.S. savings and investment in the last three decades, as the demand and supply responses tend to offset each other. See also the survey chapter inObstfeld and Rogoff (1996) for a review of the macroeconomic consequences of changes in population growth rates in traditional overlapping generation models.

Through their effect on the real interest rate, demographic trends can thus be one of the key drivers of the so-called "Secular Stagnation" hypothesis (Hansen, 1939). In resuscitating this idea, Summers (2014) has emphasized exactly how in such an environment the equilibrium real interest rate would be low, and potentially negative. Low and declining real interest rates carry important implications for the conduct of monetary policy, especially in light of the zero lower bound on monetary policy. The paper briefly revisits this issue in the context of our framework.

In addition to the diagnostics, the literature on Secular Stagnation puts forth policy suggestions to ameliorate the problems it highlights. Our analysis formalizes some of these ideas, and allows us to quantify the effects of specific measures that, at least in principle, can undo or mitigate the effects of the demographic transition on real rates, such as expansionary fiscal policies and structural reforms.

The rest of the paper proceeds as follows. Section 2 presents the model, with particular focus on the life-cycle dimension. Section 3 provides some anecdotal evidence on possible links between demographics and real interest rates, and presents our quantitative experiments based on the calibrated model. Section 4 studies policies that may mitigate or undo the effects of the demographic transition on real interest rates. Finally, Section 5 concludes.

2 The Model

The economy consist of three types of economic agents: households, firms, and the government. Individuals are born workers, and supply inelastically one unit of labor while employed. After retirement, households consume out of their asset income. The two available saving vehicles are physical capital and government bonds. Perfectly competitive firms produce a single good (the numeraire) that is used for both consumption and investment. The government takes spending as given and decides on the mix of lump-sum taxes and one-period debt to satisfy its budget constraint.

We abstract from aggregate uncertainty and consider the effects of unexpected one-time changes in demographic parameters in an otherwise perfect-foresight environment. The only source of uncertainty that may potentially affect agents' behavior stems from idiosyncratic retirement and death risk. To keep the model tractable, we make a few assumptions that simplify aggregation without sacrificing the life-cycle dimension.

2.1 Households and Life-Cycle Structure

At any given point in time, individuals belong to one of two groups: workers (w) or retirees (r). At time $t-1$, workers have mass N^w_{t-1} and retirees have mass N^r_{t-1}. Between periods $t-1$ and t, a worker remains in the labor force with probability ω_t, and retires otherwise. If retired, an individual survives from period $t-1$ to period t with probability γ_t.[4] In period t, $(1-\omega_t+n_t)\,N^w_{t-1}$ new workers are born. Consequently, the law of motion for the aggregate labor force is

$$N^w_t = (1-\omega_t+n_t)\,N^w_{t-1} + \omega_t N^w_{t-1} = (1+n_t)\,N^w_{t-1}, \tag{1}$$

[4]Because retirement is an absorbing state in this model, the probability of retiring is perhaps best interpreted as the risk of becoming unable to supply labor.

so that n_t represents the growth rate of the labor force between periods $t-1$ and t. The number of retirees evolves over time according to

$$N_t^r = (1-\omega_t)\, N_{t-1}^w + \gamma_t N_{t-1}^r. \tag{2}$$

From (1) and (2), we define the dependency ratio ($\psi_t \equiv N_t^r/N_t^w$), which summarizes the relevant heterogeneity in the population and evolves according to

$$(1+n_t)\,\psi_t = (1-\omega_t) + \gamma_t \psi_{t-1}. \tag{3}$$

Workers inelastically supply one unit of labor, while retirees do not work.[5] Preferences for an individual of group $z = \{w, r\}$ are a restricted version of the recursive non-expected utility family (Kreps and Porteus, 1978; Epstein and Zin, 1989) that assumes risk neutrality

$$V_t^z = \left\{ (C_t^z)^\rho + \beta_{t+1}^z \left[E_t \left(V_{t+1} \mid z \right) \right]^\rho \right\}^{\frac{1}{\rho}}, \tag{4}$$

where C_t^z denotes consumption and V_t^z stands for the value of utility in period t. Retirees and workers have different discount factors to account for the probability of death

$$\beta_{t+1}^z = \begin{cases} \beta \gamma_{t+1} & \text{if } z = r \\ \beta & \text{if } z = w \end{cases}$$

The expected continuation value in (4) differs across workers and retirees because of the different possibilities to transition between groups

$$E_t \left\{ V_{t+1} \mid z \right\} = \begin{cases} V_{t+1}^r & \text{if } z = r \\ \omega_{t+1} V_{t+1}^w + (1-\omega_{t+1})\, V_{t+1}^r & \text{if } z = w \end{cases}$$

This life-cycle model is analytically tractable because the transition probabilities ω and γ are independent of age and of the time since retirement. With standard risk-averse preferences, however, this assumption would imply a strong precautionary saving motive for young agents, which is hard to reconcile with actual consumption/savings choices. Risk-neutral preferences with respect to income fluctuations prevent a counterfactual excess of savings by young workers (Farmer, 1990; Gertler, 1999). Nevertheless, the separation of the coefficient of intertemporal substitution ($\sigma \equiv (1-\rho)^{-1}$) from risk aversion implied by (4) allows for a reasonable response of consumption and savings to changes in interest rates.

Households consume the final good C_t and allocate their wealth among investment in new physical capital K_t and bonds issued by the government B_t. Households rent the capital stock to firms at a

[5] Gertler (1999) shows how to introduce variable labor supply in this framework without sacrificing its analytical tractability. The demographic trends documented in Section 1 should induce individuals to supply more hours and increase participation rates. The data for all advanced economies, instead, display the opposite tendency, that is, a more or less pronounced downward trend for both variables. We thus view the assumption of inelastic labor supply as a natural benchmark for the purposes of our paper. At the same time, government policies around the world are attempting to fight this course, delaying the retirement age. We return to this issue toward the end of the paper.

real rate R_t^K and bear the cost of depreciation $\delta \in (0,1)$. Government bonds B_t pay a gross return R_t.

2.1.1 Retirees

An individual born in period j and retired in period τ chooses consumption $C_t^r(j,\tau)$ and assets $K_t^r(j,\tau)$, $B_t^r(j,\tau)$, for $t \geq \tau$ to solve

$$V_t^r(j,\tau) = \max \left\{ \left(C_t^r(j,\tau)\right)^\rho + \beta\gamma_{t+1}\left[V_{t+1}^r(j,\tau)\right]^\rho \right\}^{\frac{1}{\rho}}, \tag{5}$$

subject to

$$C_t^r(j,\tau) + K_t^r(j,\tau) + B_t^r(j,\tau) = \frac{1}{\gamma_t}\left\{[R_t^K + (1-\delta)]K_{t-1}^r(j,\tau) + R_{t-1}B_{t-1}^r(j,\tau)\right\}. \tag{6}$$

Additionally, the optimization problem is also subject to the consistency requirement that the retiree's initial asset holdings upon retirement correspond to the assets held in the last period as a worker, that is,

$$\begin{aligned} K_{\tau-1}^r(j,\tau) &= K_{\tau-1}^w(j), \\ B_{\tau-1}^r(j,\tau) &= B_{\tau-1}^w(j). \end{aligned} \tag{7}$$

At the beginning of each period, retirees turn their wealth over to a perfectly competitive mutual fund industry which invests the proceeds and pays back a premium over the market return equal to $1/\gamma_t$, to compensate for the probability of death (Blanchard, 1985; Yaari, 1965). A retiree who survives between periods $t-1$ and t then makes investment decisions right at the end of period $t-1$.

Appendix A.1 derives the Euler equations for government bonds and capital that characterize the problem of a retiree. In the absence of aggregate uncertainty, returns on both assets are equalized

$$R_t = R_{t+1}^K + (1-\delta). \tag{8}$$

Hence, for convenience, we define total assets for a retiree as

$$A_t^r(j,\tau) \equiv K_t^r(j,\tau) + B_t^r(j,\tau). \tag{9}$$

Due to the equality of returns, a retiree's budget constraint (6) can be rewritten compactly as

$$C_t^r(j,\tau) + A_t^r(j,\tau) = \frac{R_{t-1}A_{t-1}^r(j,\tau)}{\gamma_t}. \tag{10}$$

In Appendix A.1 we show that consumption is a fraction of total wealth

$$C_t^r(j,\tau) = \xi_t^r\left(\frac{R_{t-1}A_{t-1}^r(j,\tau)}{\gamma_t}\right), \tag{11}$$

where the marginal propensity to consume satisfies the following first-order non-linear difference equa-

tion:
$$\frac{1}{\xi_t^r} = 1 + \gamma_{t+1}\beta^{\sigma} \left(R_t\right)^{\sigma-1} \frac{1}{\xi_{t+1}^r}. \tag{12}$$

From (11) and (10), asset holdings evolve according to

$$A_t^r(j,\tau) = \left(1 - \xi_t^r\right) \frac{R_{t-1}A_{t-1}^r(j,\tau)}{\gamma_t}.$$

Finally, the Appendix also shows that the value function for a retiree is linear in consumption

$$V_t^r\left(j,\tau\right) = \left(\xi_t^r\right)^{\frac{\sigma}{1-\sigma}} C_t^r\left(j,\tau\right). \tag{13}$$

2.1.2 Workers

Workers start their life with zero assets. We write the optimization problem for a worker born in period j in terms of total assets $A_t^w\left(j\right) \equiv K_t^w(j) + B_t^w(j)$. Specifically, a worker chooses consumption $C_t^w\left(j\right)$ and assets $A_t^w\left(j\right)$ for $t \geq j$ to solve

$$V_t^w\left(j\right) = \max \; \left\{ \left(C_t^w\left(j\right)\right)^{\rho} + \beta \left[\omega_{t+1}V_{t+1}^w\left(j\right) + \left(1-\omega_{t+1}\right)V_{t+1}^r\left(j,t+1\right)\right]^{\rho} \right\}^{\frac{1}{\rho}}, \tag{14}$$

subject to

$$C_t^w\left(j\right) + A_t^w\left(j\right) = R_{t-1}A_{t-1}^w\left(j\right) + W_t - T_t^w \tag{15}$$

and $A_j^w\left(j\right) = 0$, where W_t represents the real wage and T_t^w is the total amount of lump-sum taxes paid by each worker. Workers do not turn their wealth over to the mutual fund industry, and hence do not receive the additional return that compensates for the probability of death.[6] The value function $V_{t+1}^r\left(j,t+1\right)$ is the solution of the problem (5) – (10) above and enters the continuation value of workers, who have to take into account the possibility that retirement occurs between periods t and $t+1$.

In Appendix A.2 we present the complete solution to a worker's optimization problem and show that workers' consumption is a fraction of total wealth, defined as the sum of financial and non-financial ("human") wealth

$$C_t^w\left(j\right) = \xi_t^w\left(R_{t-1}A_{t-1}^w\left(j\right) + H_t^w\right), \tag{16}$$

where H_t^w represents the present discounted value of current and future real wages net of taxation, and is independent of individual-specific characteristics

$$H_t^w \equiv \sum_{v=0}^{\infty} \frac{\left(W_{t+v} - T_{t+v}^w\right)}{\prod_{s=1}^{v} \frac{\Omega_{t+s}R_{t+s-1}}{\omega_{t+s}}} = W_t - T_t^w + \frac{\omega_{t+1}H_{t+1}^w}{\Omega_{t+1}R_t}. \tag{17}$$

As for retirees, workers' marginal propensity to consume ξ_t^w also evolves according to a first-order

[6] Allowing workers access to the mutual fund industry would provide complete insurance against the probability of retirement, hence shutting down most of the interesting life-cycle dimensions of the model.

non-linear difference equation:

$$\frac{1}{\xi_t^w} = 1 + \beta^\sigma \left(\Omega_{t+1} R_t\right)^{\sigma-1} \frac{1}{\xi_{t+1}^w}. \tag{18}$$

The adjustment term Ω_t that appears in (17) and (18) depends on the ratio of the marginal propensity to consume of retirees and workers

$$\Omega_t \equiv \omega_t + (1-\omega_t)\left(\frac{\xi_t^r}{\xi_t^w}\right)^{\frac{1}{1-\sigma}}.$$

In the definition of non-financial wealth (17), the term $\frac{\Omega_{t+1} R_t}{\omega_{t+1}}$ constitutes the real effective discount rate for a worker. The first component of the (higher) discounting captures the effect of the finite lifetime horizon (less value attached to the future). The term ω_{t+1} augments the actual discount factor because workers need to finance consumption during the retirement period (positive probability of retiring).

The dynamics of asset holdings can then be obtained from the budget constraint of a worker and the consumption function (16)

$$A_t^w(j) + \frac{\omega_{t+1} H_{t+1}^w}{\Omega_{t+1} R_t} = \left(1 - \xi_t^w\right)\left(R_{t-1} A_{t-1}^w(j) + H_t^w\right).$$

Finally, as for retirees, workers' value function is also linear in their consumption

$$V_t^w(j) = \left(\xi_t^w\right)^{\frac{\sigma}{1-\sigma}} C_t^w(j), \tag{19}$$

2.1.3 Aggregation of Households' Decisions

The marginal propensities to consume of workers and retirees are independent of individual characteristics. Hence, given the linearity of the consumption functions, aggregate consumption of workers (C_t^w) and retirees (C_t^r) have the form similar to (11) and (16)[7]

$$C_t^w = \xi_t^w \left(R_{t-1} A_{t-1}^w + H_t\right), \tag{20}$$

$$C_t^r = \xi_t^r R_{t-1} A_{t-1}^r, \tag{21}$$

where A_{t-1}^z is total financial wealth that members of group $z = \{w, r\}$ carry from period $t-1$ into period t, and the aggregate value of human wealth H_t evolves according to

$$H_t = W_t N_t^w - T_t + \frac{\omega_{t+1} H_{t+1}}{\left(1 + n_{t+1}\right) \Omega_{t+1} R_t}. \tag{22}$$

[7]An aggregate variable S_t^z for group $z = \{w, r\}$ takes the form $S_t^z \equiv \int_0^{N_t^z} S_t^z(i)\, di$.

The aggregate consumption function C_t is the weighted sum of (21) and (20). If $\lambda_t \equiv A_t^r/A_t$ denotes the share of total financial wealth A_t held by retirees, the aggregate consumption function is

$$C_t = \xi_t^w \left[(1-\lambda_{t-1}) R_{t-1}A_{t-1} + H_t\right] + \xi_t^r \left(\lambda_{t-1}R_{t-1}A_{t-1}\right). \tag{23}$$

Relative to the standard neoclassical growth model, the distribution of assets across cohorts is an additional state variable, which keeps track of the heterogeneity in wealth accumulation due to the life-cycle structure.

Aggregate assets for retirees depend on the total savings of those who are retired in period t as well as on the total savings of the fraction of workers who retire between periods t and $t+1$

$$A_t^r = R_{t-1}A_{t-1}^r - C_t^r + (1-\omega_{t+1})\left(R_{t-1}A_{t-1}^w + W_tN_t^w - T_t - C_t^w\right). \tag{24}$$

Aggregate assets for workers depend only on the savings of the fraction of workers who remain in the labor force

$$A_t^w = \omega_{t+1}\left(R_{t-1}A_{t-1}^w + W_tN_t^w - T_t - C_t^w\right). \tag{25}$$

The law of motion for the distribution of financial wealth across groups obtains from substituting expressions (21) and (25) into (24)

$$\lambda_tA_t = (1-\omega_{t+1})A_t + \omega_{t+1}(1-\xi_t^r)\lambda_{t-1}R_{t-1}A_{t-1}. \tag{26}$$

Expression (26) relates the evolution of the distribution of wealth λ_t to the aggregate asset position A_t. From expression (9) and its counterpart for workers, total assets equal the sum of the aggregate capital stock and government bonds:

$$A_t = K_t + B_t. \tag{27}$$

2.2 Firms and Production

The supply side of the model is completely standard. Competitive firms employ labor hired from households and capital rented from both workers and retirees to produce a homogeneous final good, which is used for both consumption and investment purposes. The production function is Cobb-Douglas with labor-augmenting technology.

The problem of a representative firm can be written as

$$\max_{N_t^w, K_{t-1}} \quad Y_t - \left(W_tN_t^w + R_t^K K_{t-1}\right)$$

$$s.t. \quad Y_t = (X_tN_t^w)^\alpha K_{t-1}^{1-\alpha},$$

where $\alpha \in (0,1)$ is the labor share and the technology factor X_t grows exogenously at rate x_t

$$X_t = (1+x_t)X_{t-1}.$$

The first-order conditions for labor and capital are

$$W_t N_t^w = \alpha Y_t \tag{28}$$

$$R_t^K K_{t-1} = (1-\alpha) Y_t. \tag{29}$$

2.3 Fiscal Policy

The government issues one-period debt B_t and levies lump-sum taxes to finance a given stream of spending G_t. The flow government budget constraint is

$$B_t = R_{t-1} B_{t-1} + G_t - T_t. \tag{30}$$

For simplicity, and to focus solely on the role of demographics to explain the decline in the real interest rate, we assume that the ratio between government spending and GDP is constant ($G_t = gY_t$). We also impose a fiscal rule that requires the government to keep a constant debt-to-GDP ratio

$$B_t = bY_t, \tag{31}$$

which implies a zero total deficit in percentage of GDP in each period. We come back to fiscal policy considerations at the end of the paper.

2.4 Equilibrium

Given the dynamics for the demographic processes n_t, ω_t, and γ_t and the growth rate of productivity x_t, a competitive equilibrium for this economy is a sequence of quantities $\{C_t^r$, C_t^w, C_t, A_t^r, A_t^w, A_t, λ_t, H_t, Y_t, K_t, I_t, V_t^r, V_t^w, B_t, $T_t\}$, marginal propensities to consume $\{\xi_t^r$, ξ_t^w, ϵ_t, $\Omega_t\}$, prices $\{R_t$, R_t^K, $W_t\}$, and dependency ratio ψ_t such that:

1. Retirees and workers maximize utility subject to their budget constraints, taking market prices as given, as outlined in sections 2.1.1 and 2.1.2.

2. Firms maximize profits subject to their technology (section 2.2).

3. The fiscal authority chooses the mix of debt and taxes to satisfy its budget constraint (section 2.3).

4. The markets for labor, capital and goods clear. In particular, the economy-wide resource constraint is

$$Y_t = C_t + I_t + G_t, \tag{32}$$

where investment I_t is defined by the law of motion of capital

$$K_t = (1-\delta) K_{t-1} + I_t. \tag{33}$$

We focus on an equilibrium with constant productivity growth (i.e. $x_t = x, \ \forall t$) and constant probability of retirement, ($\omega_t = \omega, \ \forall t$). We solve for the steady state and characterize the dynamics

Table 1: Parameter values and steady state exogenous variables.

α	=	0.67	Labor share
δ	=	0.1	Depreciation rate
σ	=	0.5	Elasticity of intertemporal substitution
x	=	0.01	Productivity growth rate
g	=	0.2	Government spending (% of GDP)
b	=	0.6	Government debt (% of GDP)
β	=	0.9631	Individual discount factor
ω	=	0.9778	Probability of remaining in the labor force
n_{1990}	=	0.0055	Initial growth rate of the labor force
γ_{1990}	=	0.8998	Initial probability of surviving
n_{2100}	=	0.0001	Initial growth rate of the labor force
γ_{2100}	=	0.9616	Initial probability of surviving

of variables expressed in efficiency units (i.e., $s_t \equiv S_t/(X_t N_t^w)$ for any variable S_t). The next section explains the experiments in details.

3 Demographics and Real Rates

This section analyzes the link between demographics and real interest rates. First, we discuss the calibration of the model and the results of the two main experiments, which consist of a decline in population growth and an increase in the survival probability. Next, we present some anecdotal evidence on the relationships between these variables. We adopt a "country-pair analysis" by comparing a few pairs of countries that share some demographic characteristics but differ in another demographic dimension.

3.1 Calibration and Experiment

Each period corresponds to one year. Individuals are born at age 20. We calibrate the probability of remaining in the labor force ω to 0.9778, which implies an average retirement age of 65. This value is consistent with the current retirement age in the majority of OECD countries. To calibrate the initial growth rate of the labor force and probability of surviving, we use data from the United Nation World Population Prospects (the 2015 revision). The initial value of labor force growth (n) matches directly the average population growth rate for developed economies in 1990, and is only slightly lower than the growth rate in 1970 (0.77%). The initial value of γ is calibrated to match the average dependency ratio among developed economies in 1990 (equal to 21%), conditional on the values of n and ω, using the steady state model counterpart

$$\psi = \frac{1-\omega}{1+n-\gamma}.$$

The implied value (equal to 0.8998) yields an average retirement period of 10 years. Overall life expectancy, thus, corresponds to 75 years, in line with the data for life expectancy at birth among developed economies in 1970. We follow a similar approach to pin down the final values of n and γ, respectively equal to 0.0001 and 0.9616. Population growth rate in 2100 is projected to be barely

positive and the dependency ratio is expected to reach almost 58%, which returns a value of γ equal to 0.9616 in the final steady state. The average retirement period therefore increases to 26 years, and overall life expectancy rises to 91.

This "representative" transition for developed economies masks some heterogeneity among countries. For example, Japan is at one extreme of the range, with population growth rates currently in negative territory, and life expectancy well above 80. At the opposite end of the spectrum, the United States has a population growth rate just below 1% and life expectancy well below 80. This range is projected to remain roughly stable throughout the current century.

The other parameters of the model are fairly standard in the literature. The elasticity of intertemporal substitution σ is set to 0.5, consistent with the estimates in Hall (1988) and Yogo (2004). The labor share of output α equals 0.667 and the depreciation rate δ is set to 0.1, in line with the average post-war values for several advanced economies. Total factor productivity grows at 1% per year, higher than for the average TFP growth rate for G7 economies post-1990 (0.3%) but close to the value in a broader sample of OECD countries. Government spending represents 20% of GDP while government debt corresponds to 60% of GDP. These values are close to their data counterparts for G7 countries post-1990 (19.2% and 52.3% respectively). Finally, the individual discount factor β is chosen so that the real interest rate in the initial steady state equals 4%, close to the average ex-post real interest rate on short-term (maturity less than a year) government bonds for the sample of countries in Figure 1.

The main experiment consists of computing the transition from the initial steady state in 1990 to the final steady state in 2100. Demographic variables are the only exogenous drivers of the simulation.[8] We assume that n_t and γ_t follow

$$
\begin{aligned}
n_t &= n_{1990} \exp(u_{nt} - v_{nt}), \\
\gamma_t &= \gamma_{1990} \exp(u_{\gamma t} - v_{\gamma t}).
\end{aligned}
$$

where u_{it} and v_{it} (for $i = \{n, \gamma\}$) are stationary AR(1) processes with common innovation ε_{it}. We choose the persistence parameters ρ_i and the initial innovation (the only unanticipated shock) such that the implied process for population growth and the dependency ratio roughly match the data.

Figure 4 compares the evolution of the exogenous demographic variables in the model with their empirical counterparts. The left panel shows that, except for a short-lived bump, the assumed process fits the evolution of population growth in the data very closely. The right-hand side panel shows that the dependency ratio in the model is smoother than in the data, although very close for the first thirty years and the last twenty years of the sample. Given that the processes in the model aim at fitting projections, not actual data, our approach is rather conservative. In particular, the implied probability of surviving that we back out of the dependency ratio in the model corresponds to a slower aging profile than the United Nations projections currently imply. As we shall see in the next section, this approach leads to an underestimation of the effect of the demographic transition on the real interest rate. In this respect, our results represent a lower bound for the effects of the demographic transition on the real interest rate.

[8]The solution is obtained with the shooting algorithm in Dynare.

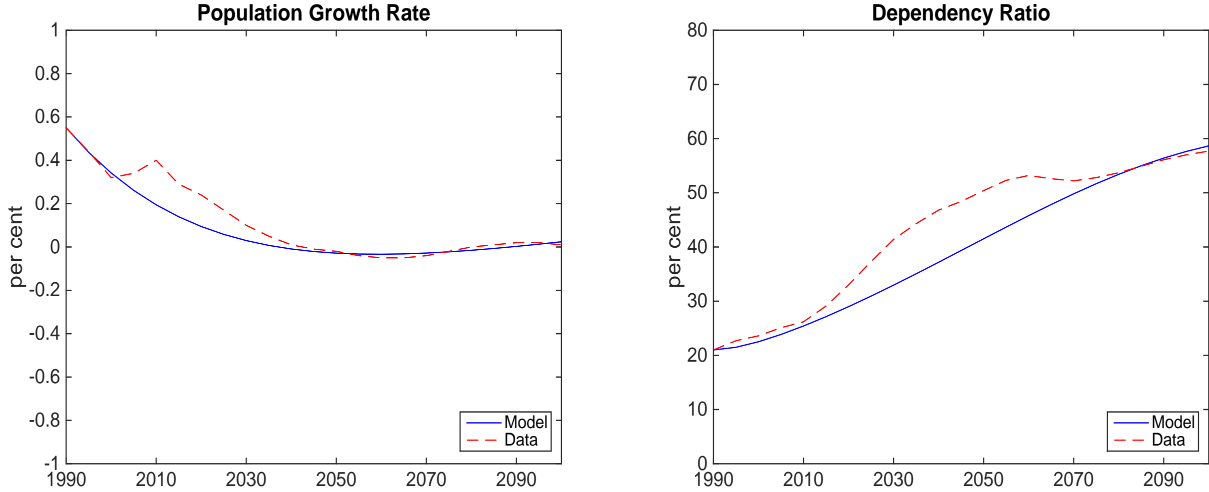

Figure 4: Left panel: Population growth rate in the model (continuous blue line) and in the data (dashed red line). Right panel: Dependency ratio in the model (continuous blue line) and in the data (dashed red line).

3.2 Effects of the Demographic Transition on the Real Interest Rate

Figure 5 shows the main result in the paper. In response to the demographic transition, the real interest rate progressively falls from 4% to approximately 2.5% between 1990 and 2014 (blue line). The model therefore explains about one third of the overall decline observed in the data. Furthermore, the simulation predicts the real interest rate will fall an additional 50 basis points over the next forty years, before stabilizing around its new steady state value of 2%.

The figure also reports the model real interest rate in two counterfactual simulations. The first (the red line) is the real interest rate implied by the decline in population growth only, holding the probability of surviving at its initial steady state value. Conversely, the second counterfactual (the green line) is the real interest rate when only the probability of surviving increases as in the baseline case, holding the population growth rate at its initial steady state value.

This decomposition represents the second important result in our paper. The increase in the probability of surviving, rather than the fall in the population growth rate, is mainly responsible for the decline in the real interest rate explained by the demographic transition.

The higher probability of surviving acts like a preference "shock" that induces retirees to save more, since this group effectively discounts the future at rate $\beta\gamma_{t+1}$ (see expression 5). But at each point in time, workers attach some probability to retirement (expression 14). Therefore, the increase in life expectancy also affects this group through their continuation value. As a result, both groups increase their savings, thus putting downward pressure on the real interest rate.

This effect can be seen analytically by differentiating the marginal propensity to consume of each group at steady state. Starting with retirees, the partial derivative of their marginal propensity to consume is

$$\frac{\partial \xi^r}{\partial \gamma} = -\beta^\sigma R^{\sigma-1}\left[1 + (\sigma - 1)\varepsilon_{R,\gamma}\right] < 0, \tag{34}$$

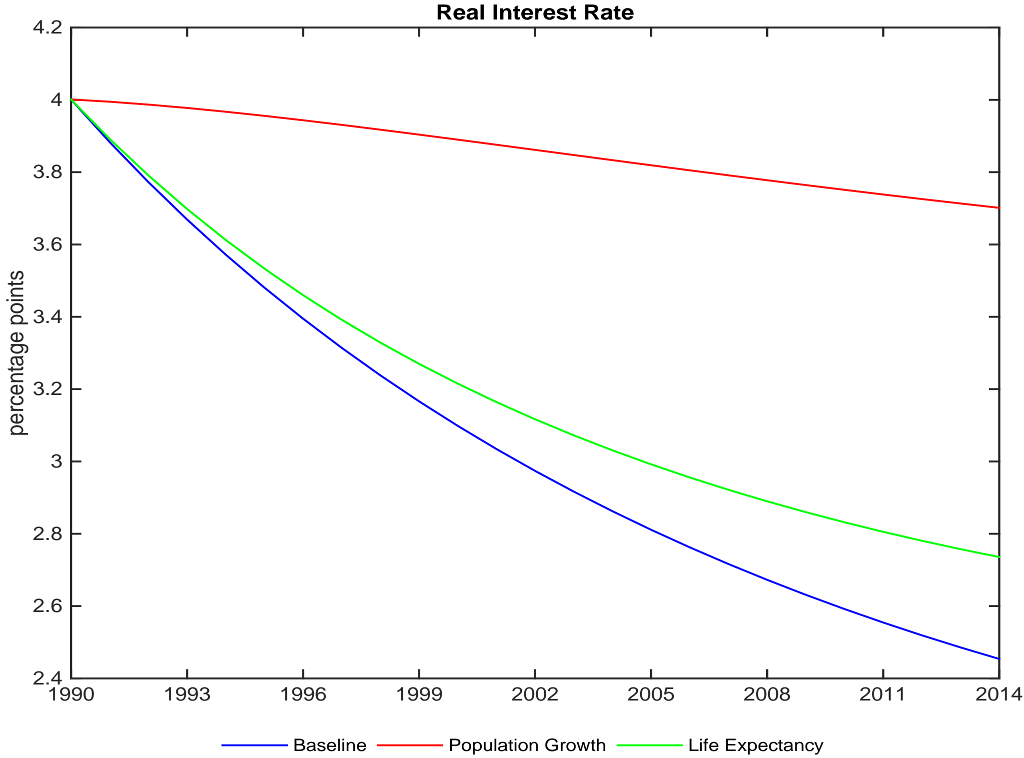

Figure 5: Simulated real interest rate following (i) the full demographic transition (blue line), (ii) only the decrease in the population growth rate (red line), (iii) only the increase in the probability of surviving (green line).

where $\varepsilon_{R,\gamma} \equiv (\partial R/R)/(\partial\gamma/\gamma) < 0$ is the elasticity of the real interest rate with respect to the probability of surviving. The first term captures the direct effect discussed above. The second one is the general equilibrium effect, as the marginal propensity to consume itself depends on the real interest rate. In this respect, the assumption that the elasticity of intertemporal substitution is smaller than one is important. With the logarithmic version of Epstein-Zin preferences (which corresponds to the case $\sigma = 1$), only the direct effect survives. And if the elasticity of intertemporal substitution were assumed to be larger than one, the general equilibrium effect would partially offset the direct one.

Using the implicit function theorem, we can also derive the effect of a change in life expectancy on the marginal propensity to consume of workers

$$\frac{\partial\xi^w}{\partial\gamma} = -\frac{\beta^\sigma(\Omega R)^{\sigma-1}\left[(\sigma-1)\varepsilon_{R,\gamma} - \left(\frac{\Omega-\omega}{\Omega}\right)\varepsilon_{\xi^r,\gamma}\right]}{\gamma\left[1+\beta^\sigma(\Omega R)^{\sigma-1}\left(\frac{\Omega-\omega}{\Omega}\right)\frac{1}{\xi^w}\right]} < 0,$$

where $\Omega - \omega = (1-\omega)\xi^r/\xi^w > 0$ and $\varepsilon_{\xi^r,\gamma} \equiv (\partial\xi^r/\xi^r)/(\partial\gamma/\gamma) < 0$ because of (34) above. The assumption that the elasticity of intertemporal substitution is smaller than one, while not crucial, strengthens the result also in this case.

The two top panels of Figure 6 show the quantitative importance of the effect of an increase in the probability of surviving on the marginal propensity to consume of workers and retirees respectively.

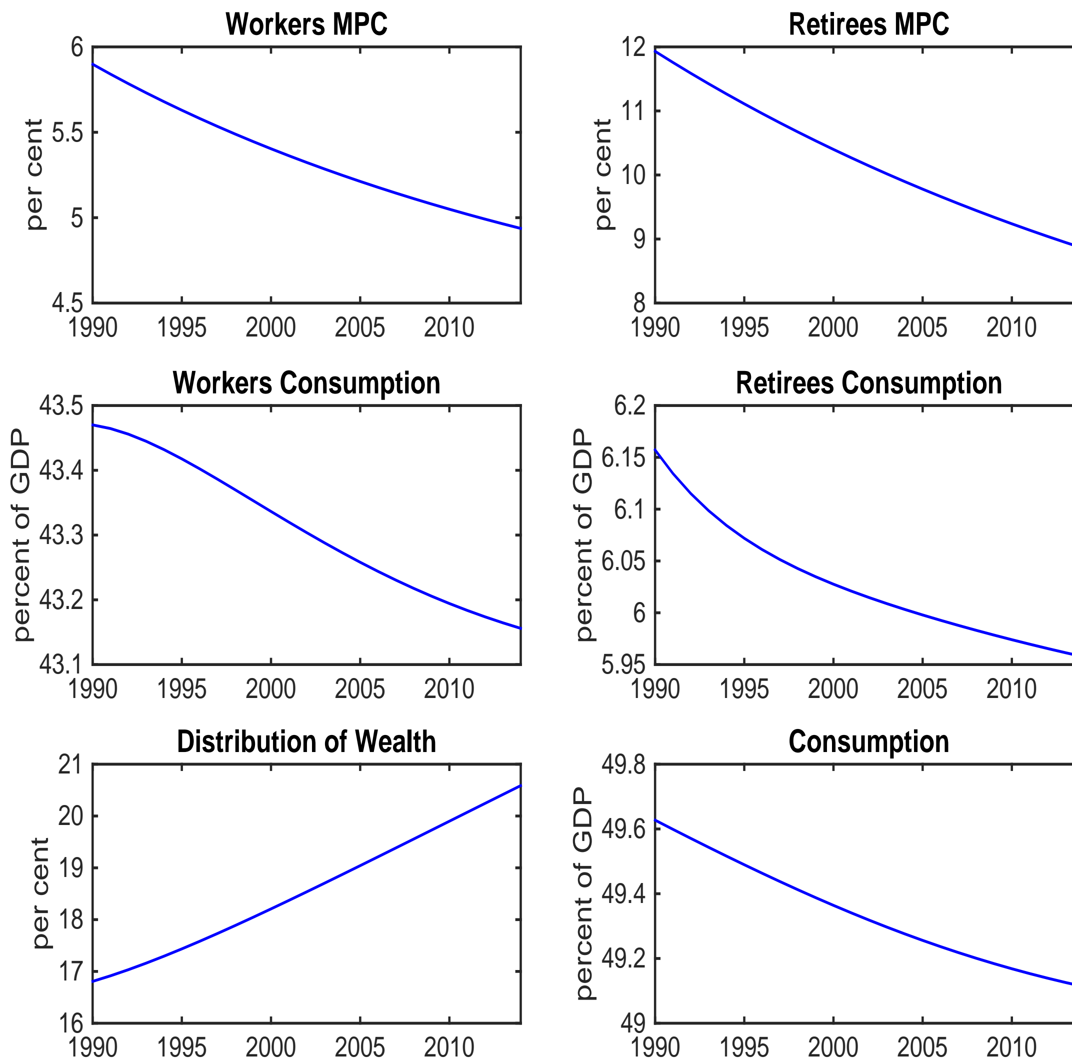

Figure 6: Simulated marginal propensity to consume for workers (top left) and retirees (top right), consumption for workers (middle left) and retirees (middle right), distribution of wealth (bottom left), and aggregate consumption (bottom right), in response to the increase in the probability of surviving.

The marginal propensity to consume of retirees remains higher than the workers' one, but it falls by more (about one fourth against one sixth). Retirees, however, hold more assets, therefore their consumption falls less (middle panels). In fact, the larger decline in the marginal propensity to consume of retirees implies that their asset accumulation is proportionally larger than for workers, so that the distribution of wealth shifts in favor of the former group (top right panel). In the aggregate, consumption falls by about half a percentage point (bottom right panel). Therefore, the demographic transition—and in particular the higher probability of surviving– does not carry large consequences for macroeconomic aggregates. Rather, it is the real interest rate that bears the bulk of the adjustment.

The other notable aspect of the demographic transition is the fall in the population growth rate. As mentioned, the repercussions for the real interest rate are quantitatively less significant than those of the increase in life expectancy. The intuition is that a falling population growth rate brings about two effects working in opposite directions. On the one hand, a lower population growth rate reduces the pool of workers, thus increasing the capital-labor ratio. Therefore, the rental rate decreases, and, by no arbitrage, so does the real rate. On the other hand, however, a lower population growth rate progressively increases the dependency ratio—the ratio of retirees to workers. Because retirees have a larger marginal propensity to consume, this effect tends to offset the consequence of the less efficient use of capital. Overall, the effect is negative, but quantitatively small. This finding is therefore consistent with the view that the negative effects of the demographic transition on the real interest rate may be small and temporary (see, for example, Erfurth and Goodhart, 2014). However, this conclusion neglects the key role of the increase in life expectancy that this paper highlights.[9]

3.3 Suggestive Anecdotal Evidence

The model just presented suggests different possible links between demographics and real interest rates. Here we resort to country-pair comparisons to provide some anecdotal evidence of these relationships in the data. The key result from the model is that the demographic transition—and, in particular, the increase in life expectancy—drives the decline in real interest rate observed during the last two and half decades. Therefore, in the data, we compare how the short-term real interest rate varies for pairs of countries that differ only in terms of life expectancy, either actual or projected. We want to stress that this exercise is purely illustrative, and by no means aims to provide definitive empirical evidence on these patterns.

To perform our analysis, we consider data for two base years, 1990 and 2005. In particular, we calculate five-year averages, centered at 1990 and 2005, of the short-term real interest rate and life expectancy. To calculate the projected change in life expectancy, we consider the United Nations forecast for life expectancy in two 15-year windows, between 1990 and 2005 (as of 1990), and 2005 and 2020 (as of 2005).[10]

Figure 7 reports the first set of country-pairs. The figure shows short-term real rates and life expectancy for pairs of countries with similar projected change in life expectancy at the indicated base-year. For example, in 1990, Thailand and Singapore had similar projected change in life expectancy, but differed in their short term rates and life expectancy. Singapore had higher life expectancy and lower short-term yields. Similar patterns hold for other country-pairs, such as Egypt-Tunisia in 2005, and India-Indonesia in the same year. All three pairs of countries featured similar projected changes in life expectancy, and the country with higher life expectancy also had lower short-term real interest rates. Obviously, we can easily find exceptions. For example, the comparison between India and Colombia in 2005, deviates from the pattern highlighted above. In 2005, Colombia and India had

[9]Our paper focuses on the savings margin. Recent results on the detrimental effects of lower population growth on labor supply and participation rates (Fujita and Fujiwara, 2014), and on innovation (Aksoy et al., 2015) are thus complementary to our work. Eggertsson and Mehrotra (2014) show how a decline in population growth rate can be equivalent to a tightening of borrowing constraints, and thus reduce the equilibrium real interest rate.

[10]For all country-pairs reported in this exercise, the two countries in each comparison also have similar old dependency ratios (calculated as five-year averages centered at 1990 and 2005).

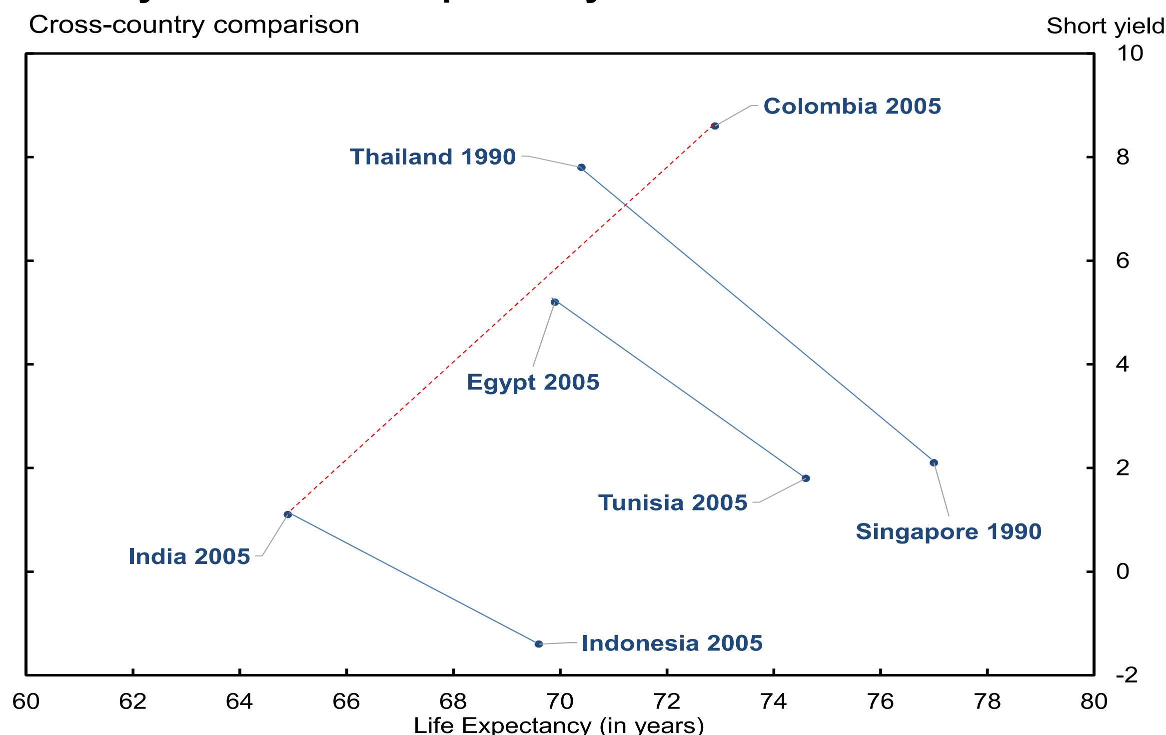

Figure 7: Short-term real rates and life expectancy: cross-country comparison.

similar projected changes in life expectancy, but Colombia had higher life expectancy and higher short-term real rates than India.

Figure 8 examines the relationship between short-term real yields and projected changes in life expectancy, for pairs of countries with similar life expectancy. The figure shows that, for example, around 1990, South Korea had a larger projected increase in life expectancy and a lower short-term real yields than Chile. Again, exceptions are not hard to find. South Korea's yield however, was higher than Mexico's, despite also having a larger projected increase in life expectancy.

The patterns reported in Figures 7 and 8 hint that the connections between demographics and real rates might be discernible in the data. However, the exceptions illustrate the challenges in determining empirically the overall impact of demographics on real interest rates. For some of the pairs that we presented, the differences in country-specific factors are so obvious that introspection should suffice to become convinced several other elements must matter for our analysis. But even for pairs of countries that may "look alike," omitted variables are likely to play a role. For example, the comparisons depicted in Figures 7 and 8 abstract from other macroeconomic factors, such as countries' indebtedness, credit ratings, productivity growth, etc. An unconditional analysis has little chance to reach a clearcut conclusion on the links between demographics and real interest rates. Despite these challenges, the anecdotal evidence suggests that some of the patterns implied by the model might be discernible in simple cross-country comparisons. This consideration suggests a potentially fruitful avenue for future empirical research on this question.

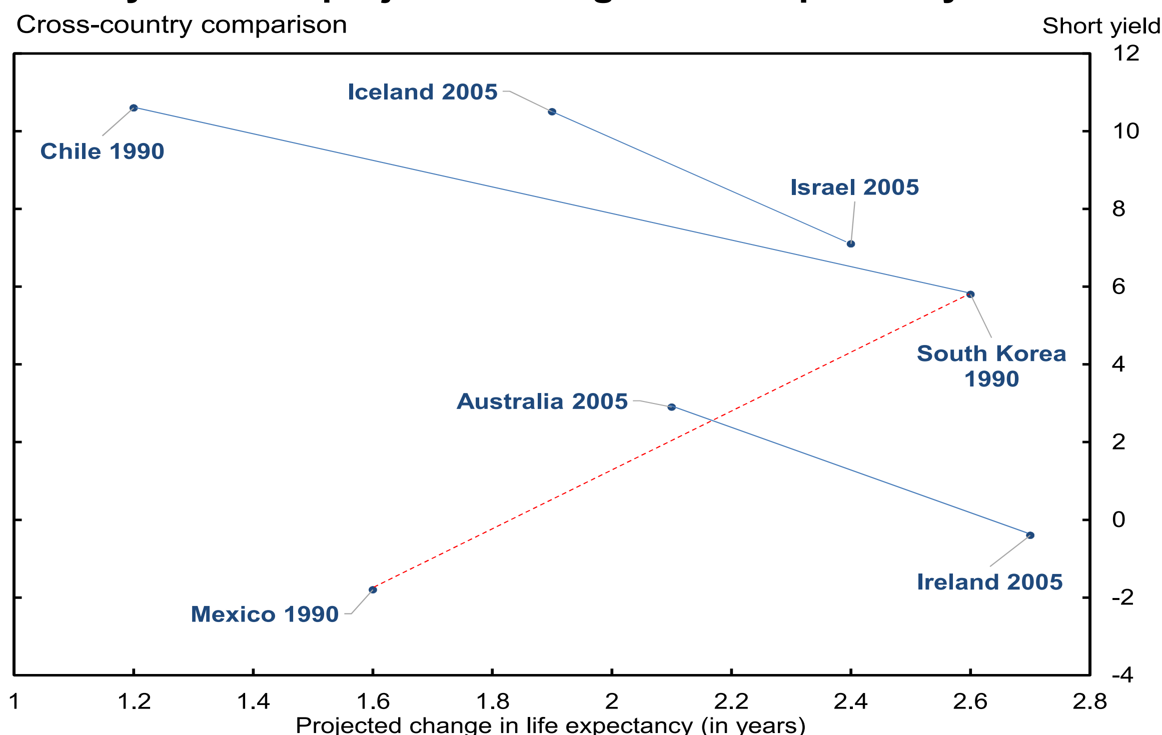

Figure 8: Short-term real rates and projected changes in life expectancy: cross-country comparison.

4 Policy Implications

An environment with a permanently low equilibrium real interest rate poses a challenge to the traditional approach to macroeconomic stabilization. This consideration should lead policymakers to reconsider the appropriate mix of monetary and fiscal interventions, as well as to entertain the possibility of using other policy instruments. In this section, we discuss some of these issues, keeping in mind that other factors besides demographics can push the equilibrium real interest rate to low levels—and possibly into negative territory.

4.1 Monetary Policy

A low and declining equilibrium real interest rate carries two important implications for monetary policy. First, as discussed, for instance, by Ball (2013) and Krugman (2014), central banks may be forced to reconsider their inflation targets. In a world where the average equilibrium real interest rate is 2%, a 2% inflation target implies an average nominal interest rate of 4%. If, however, the equilibrium real interest rate falls to zero, perhaps due a combination of demographic trends and other forces, the resulting average nominal interest rate now becomes 2%. All of a sudden, the room for central banks to respond to recessionary shocks has shrunk considerably. And this type of large shocks may actually be more frequent than previously thought, as the recent financial crisis has painfully demonstrated.

A natural approach to counter this undesirable side-effect of the demographic transition on monetary policy is to raise the inflation target. However, the benefits of higher inflation must be weighted against its welfare costs, such as those stemming from higher price dispersion (e.g., Ascari and Sbordone 2014).

A second implication is perhaps slightly more subtle. In the baseline three-equation New Keynesian model (Clarida et al., 1999; Woodford, 2003), optimal monetary policy requires the nominal interest rate to track at each point in time the so-called "efficient real interest rate". While specific details may differ, this result generalizes to most frameworks with nominal rigidities. In this class of models, the efficient real interest rate is the real interest rate that would prevail absent nominal rigidities and markup shocks—that is, the real interest rate that arises in a frictionless environment. In the baseline model, the efficient real interest rate is a combination of technology and preference shocks. In larger frameworks, other exogenous disturbances (e.g. the investment-specific technology shock) also affect this variable.

The key point is that all the aforementioned structural shocks are typically assumed to be stationary. As this paper demonstrates, the demographic transition induces variations in the efficient real interest rate that are instead likely to be permanent, especially those associated with the increase in life expectancy. These permanent developments have to be taken into account by the Central Bank. Carvalho and Ferrero (2014) explore this connection between demographic developments and monetary policy in an application to Japan, using the same framework as in this paper augmented with nominal rigidities. Their calibration to the Japanese demographic transition induces a fall in the efficient real interest rate between two and three percentage points between 1990 and 2014. If the central bank fails to adjust the nominal interest rate to the low frequency movements in the efficient real interest rate induced by demographics, monetary policy is systematically too tight, and deflation arises in equilibrium. Quantitatively, the model can account for the persistence of Japanese deflation since the early 1990s.

4.2 Fiscal Policy

Whether to bailout banks or to provide economic stimulus (or both), governments of several advanced and emerging market economies responded to the GFC with expansionary fiscal policies. As a consequence, current levels and projected paths of public debt relative to GDP have notably shifted upward and are projected to remain high for the next few years (Figure 9). Should this increase in debt become permanent, this policy would—perhaps unintentionally—counterbalance some of the effects of the demographic transition on real rates. For example, Summers (2014) has recently been an advocate of debt-financed spending, pushing the idea that, in a secular stagnation environment, government demand can substitute for private demand.

We can use our model to find the increase in the level of debt to GDP required to undo the effects demographics on the equilibrium real interest rate. In the final steady state of our simulations, the real interest rate stabilizes around 2%. The comparative statics exercise involves keeping the ratio of government spending to GDP at 20%, and finding the level of debt to GDP that brings the real interest rate back to 4%. In our calibrated model, the debt-to-GDP ratio can reach 210% before the real interest rate returns to 4%.

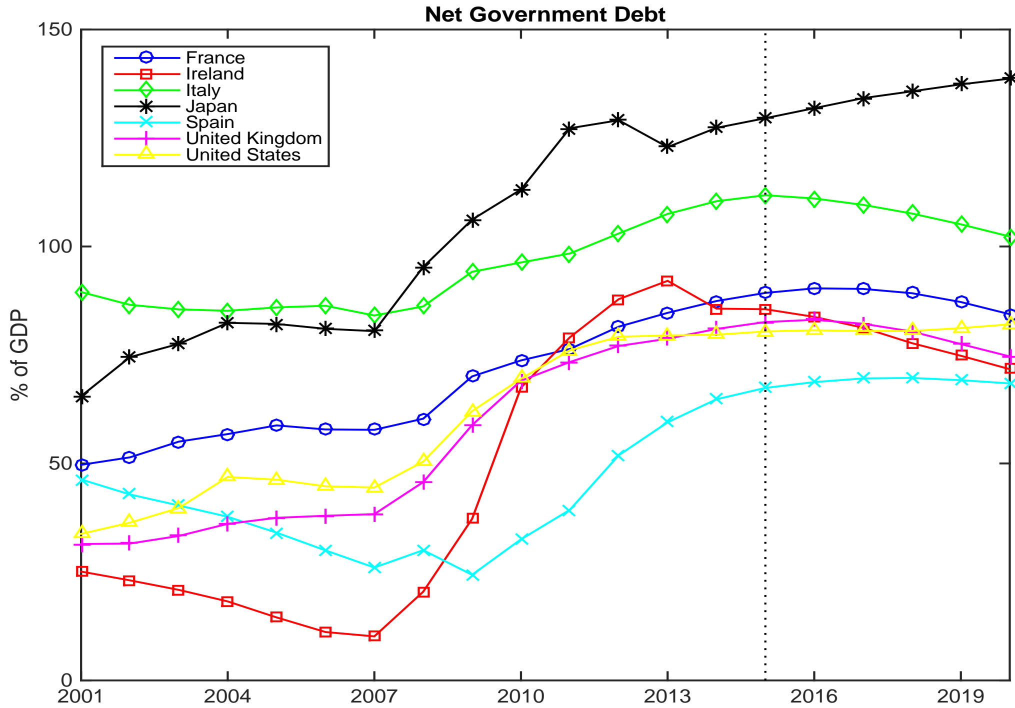

Figure 9: Ratio of net government debt to GDP. Sample: France, Ireland, Italy, Japan, Spain, United Kingdom and United States. Source: IMF World Economic Outlook Database April 2015.

Our calculations are arguably an upper bound on the required debt expansion, because the simulations do not take into account the increase in risk premia that are typically associated with large increases in government indebtedness, as the recent experience in the European periphery suggests. At the same time, however, the model returns a value of debt to GDP that is not too far from the levels currently observed in Japan—a country where the consequences of high levels of debt for risk premia appear to be very modest, but where the effects of the demographic transition are most visible.

4.3 Structural Reforms

This section considers two types of "structural reforms" that can contribute to directly increase the equilibrium real interest rate. The first is an unspecified reform that increases the growth rate of productivity—which is a parameter in the model. The second is an increase in the (average) retirement age, which is also controlled by a parameter in the model—the probability of retirement.

So far, in our simulations, we have kept the value of productivity growth fixed at 1%. This number is actually on the high side for the largest advanced economies in the world. Recently, the literature has been debating to which extent the secular stagnation hypothesis could also involve a supply-side element. For example, Gordon (2012) suggests that the period between 1750 and 2000 may have been unique in the history of economic growth, thanks to several inventions that dramatically changed the

Table 2: Retirement age by sex among OECD economies. Source: OECD (2010).

Country	Male	Female	About to change?	Note
Australia	65	63	Yes	Raised to 65 by 2014 for women; Both sexes to 67 in stages between 2017 and 2023
Austria	65	60	No	
Belgium	65	65	No	
Canada	65	65	No	Early pension can be claimed from age 60
Chile	65	60	No	
Czech Republic	62	61	Yes	Increased to 63 for men from 2016 and for women without children from 2019*
Denmark	65	65	Yes	Proposal to raise to 67 over eight years starting in 2017
Finland	63	63	No	Can be up to age 68
France	60	60	Yes	Raised to 62 by 2018
Germany	65	65	Yes	Raised to 67 between 2012 and 2029
Greece	65	60	Yes	Plans to increase to 65 for women
Hungary	62	62	Yes	Increase to 65 for men from 2018 and for women from 2020
Iceland	65	65	No	Private sector is 67
Ireland	65	65	No	No fixed age for private employees
Italy	65	60	No	
Japan	60	60	Yes	Gradually raised to 65 between 2001 and 2013 for men and 2006 and 2018 for women
Korea	60	60	Yes	Will gradually reach 65 by 2023
Luxembourg	60	60	No	Retirement at 57 is possible
Mexico	65	65	No	Early retirement available at 60
Netherlands	65	65	No	Plans to increase to 67
New Zealand	65	65	No	
Norway	67	67	No	60% of employees are entitled to early retirement at 62
Poland	65	60	No	Teachers and army forces entitled to early retirement
Portugal	65	65	No	Early retirement possible from age 55 in some circumstances
Slovakia	62	57	Yes	Increase to 62 for women by 2014
Spain	65	65	No	
Sweden	61	61	No	Flexible, state pensions can be claimed starting at 61
Switzerland	65	64	No	
Turkey	60	58	Yes	Plans to increase to 65 by 2035 for both sexes
United Kingdom	65	60	Yes	Plans to increase to 65 over 2010-2020 for women†
United States	66	66	Yes	Increasing to 67 in stages

*Increase from 59 to 62 for women with children, depending on number of children.
†State pensions at 66 in 2024, 67 in 2034 and 68 in 2044.

global environment. Subsequent work by the same author (Gordon, 2014) forecasts real output per capita to grow at 0.9% over the next thirty years.[11]

Similarly to what we have done for fiscal policy, we can use the model to find the level of productivity growth rate that would restore a 4% real interest rate, starting from a steady state in which the demographic transition has completed its course. Interestingly, the answer is that a growth rate of 2% (up from 1%) would be enough to raise the real interest rate by about two percentage points.[12] This result has two sides to it. On the "comforting" side, the increase in productivity growth necessary to counteract demographic (and other) forces that put downward pressure on the real interest rate is not massive. Indeed, it would be enough to go back to growth rates that prevailed not so long ago. However, on the negative side, one worrying argument is that productivity slowdowns often occur after deep crises. After all, the secular stagnation idea originated after the Great Depression. Together with (and perhaps because of) the financial crisis, Japan has experienced a dramatic slowdown in productivity growth since 1990 (Hayashi and Prescott, 2002). Today, the global economy is still experiencing the consequences of the GFC. The study of possible interactions between persistent lack of demand and a technological slowdown seems more timely than ever.

The second policy that we consider is the possibility that, in response to the demographic transition, the government increases the retirement age. Table 2 shows that several countries in the world are currently taking steps in this direction. In most cases, the increase in the retirement age is meant to address fiscal problems (unsustainable public pension systems). But the demographic transition is

[11]Needless to say, this view is far from representing any form of consensus (see, for example, Brynjolfsson and McAfee, 2014, for an opposite perspective).

[12]Of course any quantitative result depends on the calibration of the model. In particular, results could be relatively sensitive to changes in the elasticity of intertemporal substitution.

often the deep cause of such fiscal imbalances. As life expectancy increases, social security agencies need to pay pensions to individuals for a longer period of time. Obviously, this problem is more severe in defined-benefit systems of advanced economies, where shrinking generations of workers are responsible for the pensions of larger pools of retirees. In this paper, we abstract from the fiscal dimension, as individuals save for their own retirement and the government balances the budget given a stream of exogenous (wasteful) spending.[13]

We assume that the government increases the retirement age by manipulating the probability to retire ω, and we perform a comparative static exercise similar to the ones for fiscal policy and productivity. An increase of two years in the retirement age—a typical reform currently being implemented in advanced economies—leads to a rather modest rise (10 basis points) in the real interest rate. Conversely, the reform that fully offsets the decline in the real interest rate due to the demographic transition would be enormous, requiring an average employment period of 105 years.[14] While this result is obviously unrealistic, the overall message of the exercise is clear. While structural reforms that increase the retirement age go in the right direction to compensate the negative effects of the demographic transition on the real interest rate, these policies should not be used in isolation.

5 Conclusion

The demographic transition that all advanced economies are currently experiencing is one key element that explains the prolonged decline of global real interest rates. The main channel through which demographics affect real interest rate is the increase in life expectancy. At all stages of their life cycle, individuals save more to finance consumption over a longer time horizon. Quantitatively, the demographic transition can account for about one third of the overall decline in the real interest rate since 1990. We have provided some anecdotal evidence that the data support the importance of this channel, and discussed several policy implications.

Going forward, our research agenda on this topic consists of fully exploring the empirical dimension of this question, revisiting historical episodes of the connection between low interest rates and demographic changes, and studying its political-economic consequences.

[13] Gertler (1999) introduces social security benefits for retirees in his model.

[14] A more sensible implementation of this reform would consist of indexing the retirement age to life expectancy, perhaps through periodic revisions. Yet, the elasticity of the indexation scheme would still need to be quite high.

A Model Solution

A.1 Retirees

The first-order conditions with respect to capital and government bonds are, respectively,

$$
\begin{aligned}
\left(C_t^r(j,\tau)\right)^{\rho-1} &= \beta\gamma_{t+1}\left(V_{t+1}^r(j,\tau)\right)^{\rho-1}\frac{\partial V_{t+1}^r(j,\tau)}{\partial K_t^r(j,\tau)}\\
\left(C_t^r(j,\tau)\right)^{\rho-1} &= \beta\gamma_{t+1}\left(V_{t+1}^r(j,\tau)\right)^{\rho-1}\frac{\partial V_{t+1}^r(j,\tau)}{\partial (B_t^r(j,\tau))}
\end{aligned}
$$

The envelope conditions, used to obtain the Euler equations for the retiree's problem, are

$$
\begin{aligned}
\frac{\partial V_t^r(j,\tau)}{\partial K_{t-1}^r(j,\tau)} &= \left(V_t^r(j,\tau)\right)^{1-\rho}\left(C_t^r(j,\tau)\right)^{\rho-1}\frac{R_t^K+(1-\delta)}{\gamma_t}\\
\frac{\partial V_t^r(j,\tau)}{\partial (B_{t-1}^r(j,\tau))} &= \left(V_t^r(j,\tau)\right)^{1-\rho}\left(C_t^r(j,\tau)\right)^{\rho-1}\frac{R_{t-1}}{\gamma_t}.
\end{aligned}
$$

Combining the two sets of optimality conditions yields the standard Euler equations for bonds and capital

$$
1=\beta\frac{R_t}{\pi_{t+1}}\left[\frac{C_{t+1}^r(j,\tau)}{C_t^r(j,\tau)}\right]^{-\frac{1}{\sigma}}=\beta\left[R_{t+1}^K+(1-\delta)\right]\left[\frac{C_{t+1}^r(j,\tau)}{C_t^r(j,\tau)}\right]^{-\frac{1}{\sigma}}. \tag{35}
$$

To solve the problem of retirees, guess that consumption is a fraction of total wealth

$$
C_t^r(j,\tau)=\xi_t^r\left(\frac{R_{t-1}A_{t-1}^r(j,\tau)}{\gamma_t}\right). \tag{36}
$$

Substitution into the Euler equation (35) yields a law of motion for the marginal propensity to consume of a retiree ξ_t^r

$$
\xi_{t+1}^r\left(\frac{R_tA_t^r(j,\tau)}{\gamma_{t+1}}\right)=\left(\beta R_t\right)^{\sigma}\xi_t^r\left(\frac{R_{t-1}A_{t-1}^r(j,\tau)}{\gamma_t}\right). \tag{37}
$$

Substitution of the guess (36) into the budget constraint of a retiree (10) leads to the expression below for the dynamics of asset holdings

$$
A_t^r(j,\tau)=\left(1-\xi_t^r\right)\frac{R_{t-1}A_{t-1}^r(j,\tau)}{\gamma_t}.
$$

Combining the last expression with the law of motion for the marginal propensity to consume of a retiree (37) yields the first-order non-linear difference equation for ξ_t^r (12) in the text.

Moreover, conjecture that the value function is linear in consumption

$$
V_t^r(j,\tau)=\Delta_t^rC_t^r(j,\tau). \tag{38}
$$

Then, from (5), it must be the case that

$$\left(\Delta_t^r C_t^r(j,\tau)\right)^\rho = \left(C_t^r(j,\tau)\right)^\rho + \beta\gamma_{t+1}\left(\Delta_{t+1}^r C_{t+1}^r(j,\tau)\right)^\rho.$$

Substituting for consumption at $t+1$ from (35) and simplifying yields

$$\left(\Delta_t^r\right)^\rho = 1 + \gamma_{t+1}\beta^\sigma\left(R_t\right)^{\sigma-1}\left(\Delta_{t+1}^r\right)^\rho.$$

From (12), it then follows that the proportionality term in (38) is

$$\Delta_t^r = \left(\xi_t^r\right)^{\frac{\sigma}{1-\sigma}}.$$

A.2 Workers

The first-order condition for workers' asset holdings is

$$\left(C_t^w(j)\right)^{\rho-1} = \beta\left[\omega_{t+1}V_{t+1}^w(j) + \left(1-\omega_{t+1}\right)V_{t+1}^r(j,t+1)\right]^{\rho-1} \left[\omega_{t+1}\frac{\partial V_{t+1}^w(j)}{\partial A_t^w(j)} + \left(1-\omega_{t+1}\right)\frac{\partial V_{t+1}^r(j,t+1)}{\partial A_t^w(j)}\right].$$

The envelope conditions are for the worker's problem are

$$\frac{\partial V_t^w(j)}{\partial A_{t-1}^w(j)} = \left(V_t^w(j)\right)^{1-\rho}\left(C_t^w(j)\right)^{\rho-1}R_{t-1}$$

and

$$\frac{\partial V_t^r(j,t)}{\partial A_{t-1}^w(j)} = \frac{\partial V_t^r(j,t)}{\partial A_{t-1}^r(j,t)}\frac{\partial A_{t-1}^r(j,t)}{\partial A_{t-1}^w(j)} = \frac{\partial V_t^r(j,t)}{\partial A_{t-1}^r(j,t)},$$

where the last equality follows from (7)—i.e., from the initial conditions of the retirees' optimization problem.

Combining the first order condition with the envelope conditions yields an Euler equation for workers of cohort j

$$\left(C_t^w(j)\right)^{\rho-1} = \beta R_t\left[\omega_{t+1}V_{t+1}^w(j) + \left(1-\omega_{t+1}\right)V_{t+1}^r(j,t+1)\right]^{\rho-1} \left[\omega_{t+1}\left(V_{t+1}^w(j)\right)^{1-\rho}\left(C_{t+1}^w(j)\right)^{\rho-1} + \left(1-\omega_{t+1}\right)\left(V_{t+1}^r(j,t+1)\right)^{1-\rho}\left(C_{t+1}^r(j,t+1)\right)^{\rho-1}\right]. \quad (39)$$

To solve the problem of workers, conjecture that their value function has the same form as (38)

$$V_t^w(j) = \Delta_t^w C_t^w(j). \quad (40)$$

Substituting this guess back into the Euler equation (39) together with (38) leads to

$$(C_t^w(j))^{\rho-1} = \beta R_t \left[\omega_{t+1}\Delta_{t+1}^w C_{t+1}^w(j) + (1-\omega_{t+1})\Delta_{t+1}^r C_{t+1}^r(j,t+1)\right]^{\rho-1} \left[\omega_{t+1}\left(\Delta_{t+1}^w\right)^{1-\rho} + (1-\omega_{t+1})\left(\Delta_{t+1}^r\right)^{1-\rho}\right]. \quad (41)$$

Defining the adjustment term $\Omega_t \equiv \omega_t + (1-\omega_t)\left(\frac{\Delta_t^r}{\Delta_t^w}\right)^{1-\rho}$, the Euler equation becomes

$$\omega_{t+1}C_{t+1}^w(j) + (1-\omega_{t+1})\left(\frac{\Delta_{t+1}^r}{\Delta_{t+1}^w}\right)C_{t+1}^r(j,t+1) = (\beta\Omega_{t+1}R_t)^\sigma C_t^w(j). \quad (42)$$

The guess for the decision rule of a worker is

$$C_t^w(j) = \xi_t^w\left(R_{t-1}A_{t-1}^w(j) + H_t^w\right), \quad (43)$$

where human wealth H_t^w is defined in (22).

From (11), the decision rule for a retiree born in period j who just left the labor force is

$$C_t^r(j) = \xi_t^r R_{t-1}A_{t-1}^w(j).$$

Substituting the last expression into the Euler equation yields

$$\omega_{t+1}\left(A_t^w(j) + \frac{H_{t+1}^w}{R_t}\right) + (1-\omega_{t+1})\left(\frac{\Delta_{t+1}^r}{\Delta_{t+1}^w}\right)\epsilon_{t+1}A_t^w(j) = (\beta\Omega_{t+1})^\sigma (R_t)^{\sigma-1}\frac{\xi_t^w}{\xi_{t+1}^w}\left(R_{t-1}A_{t-1}^w(j) + H_t^w\right),$$

where $\epsilon_t \equiv \xi_t^r/\xi_t^w$. Using the definition of Ω_t, the last expression becomes

$$A_t^w(j) + \frac{\omega_{t+1}H_{t+1}^w}{\Omega_{t+1}R_{t+1}} = \beta^\sigma(\Omega_{t+1}R_t)^{\sigma-1}\frac{\xi_t^w}{\xi_{t+1}^w}\left(R_{t-1}A_{t-1}^w(j) + H_t^w\right). \quad (44)$$

Moreover, from the budget constraint of a worker and the guess (43), we obtain the law of motion for worker j's wealth

$$A_t^w(j) + \frac{\omega_{t+1}H_{t+1}^w}{\Omega_{t+1}R_t} = (1-\xi_t^w)\left(R_{t-1}A_{t-1}^w(j) + H_t^w\right).$$

Substituting this result back into the Euler equation (44), it follows that the marginal propensity to consume for a worker evolves according to expression (18) in the text.

Finally, the original guess of the value function (19) is valid if

$$(\Delta_t^w C_t^w(j))^\rho = (C_t^w(j))^\rho + \beta\left[\omega_{t+1}\Delta_{t+1}^w C_{t+1}^w(j) + (1-\omega_{t+1})\Delta_{t+1}^r C_{t+1}^r(j,t+1)\right]^\rho.$$

The last equation, combined with (42), yields

$$(\Delta_t^w)^\rho = 1 + \beta^\sigma(\Omega_{t+1}R_t)^{\sigma-1}\left(\Delta_{t+1}^w\right)^\rho.$$

Expression (18) then implies that

$$\Delta_t^w = (\xi_t^w)^{\frac{\sigma}{1-\sigma}}.$$

Hence, the ratio of the proportionality factors in the value function is $\Delta_{t+1}^r/\Delta_{t+1}^w = \epsilon_t^{-(1/\rho)}$ and

$$\Omega_t = \omega_t + (1-\omega_t)\,\epsilon_t^{\frac{1}{1-\sigma}}.$$
